ABSTRACT

Context. The detailed composition of most metal-poor halo stars has been found to be very uniform. However, a fraction of 20–70% (increasing with decreasing metallicity) exhibit dramatic enhancements in their abundances of carbon – the so-called carbon-enhanced metal-poor (CEMP) stars. A key question for Galactic chemical evolution models is whether this non-standard composition reflects that of the stellar natal clouds, or is due to local, post-birth mass transfer of chemically processed material from a binary companion; CEMP stars should then all be members of binary systems.

Aims. Our aim is to determine the frequency and orbital parameters of binaries among CEMP stars with and without over-abundances of neutron-capture elements – CEMP-*s* and CEMP-no stars, respectively – as a test of this local mass-transfer scenario. This paper discusses a sample of 24 CEMP-no stars, while a subsequent paper will consider a similar sample of CEMP-*s* stars.

Methods. High-resolution, low-S/N spectra of the stars were obtained at roughly monthly intervals, over a time span of up to eight years, with the FIES spectrograph at the Nordic Optical Telescope. Radial velocities of $\sim 100 \text{ m s}^{-1}$ precision were determined by cross-correlation after each observing night, allowing immediate, systematic follow-up of any variable object.

Results. Most programme stars exhibit no statistically significant radial-velocity variation over this period and appear to be single, while four are found to be binaries with orbital periods of 300–2,000 days and normal eccentricity; the binary frequency for the sample is $17 \pm 9\%$. The single stars mostly belong to the recently-identified “low-C band”, while the binaries have higher absolute carbon abundances.

Conclusions. We conclude that the nucleosynthetic process responsible for the strong carbon excess in these ancient stars is unrelated to their binary status; the carbon was imprinted on their natal molecular clouds in the early Galactic ISM by an even earlier, external source, strongly indicating that the CEMP-no stars are likely *bona fide* second-generation stars. We discuss potential production sites for carbon and its transfer across interstellar distances in the early ISM, and implications for the composition of high-redshift DLA systems.

Key words. Galaxy: formation – Galaxy: halo – Stars: chemically peculiar binaries: spectroscopic – ISM: structure

1. Introduction

Over the past few decades, the collective effort of large-scale spectroscopic surveys to identify and analyse very metal-poor (VMP; $[\text{Fe}/\text{H}] < -2.0$) and extremely metal-poor (EMP; $[\text{Fe}/\text{H}] < -3.0$) stars in the halo system of the Milky Way have provided an increasingly detailed picture of the star-to-star elemental-abundance variations that constrain the early chemical evolution of the Galaxy (Cayrel et al. 2004; Bonifacio et al. 2009); for general reviews, see Beers & Christlieb (2005); Ivezic et al. (2012); Frebel & Norris (2015).

However, chemically peculiar stars exist, the abundance patterns of which deviate markedly from those of the bulk of Population II stars. Identifying the nature and origin of these stars should enable identification of their progenitors, and lead to a

better understanding of the processes of nucleosynthesis and mass ejection that are responsible for the production of their distinctive chemical signatures. This information will constrain the nature of the very first generations of stars, prior to the dilution of these signatures by later mixing with the ISM of the Galaxy, which ultimately establishes the mean abundance trends for relatively more metal-rich stars.

A key element in this context is carbon, the first heavy element synthesised after the Big Bang, and found with increasing frequency in very metal-poor stars. Carbon-enhanced metal-poor (CEMP) stars were originally identified among the VMP and EMP stars discovered in the HK survey of Beers, Preston, & Shectman (Beers et al. 1985, 1992), and supplemented by a number of surveys since. The fraction of CEMP stars rises with decreasing iron abundance, $[\text{Fe}/\text{H}]$ (the conventional metallic-

Notes. * Stars not formally qualifying as CEMP-no stars, according to the [Ba/Fe] criterion. However, see discussion of their light-element abundance signatures in Section 2.3.

ity indicator), which makes them particularly important for studies of the very first stages of the formation and evolution of the Galactic halo.

The CEMP stars comprise a number of different sub-classes (initially defined by Beers & Christlieb 2005). The best-populated CEMP sub-classes are:

(i) The CEMP-*s* stars (indicating the presence of *s*-process elements in addition to the carbon enhancement; [C/Fe] > +0.7 and [Ba/Fe] > +1.0), the great majority of which can be accounted for by scenarios involving the transfer of enriched material from a binary companion that has passed through the asymptotic giant-branch (AGB) stage of evolution¹, and

(ii) The CEMP-no stars (indicating carbon enrichment, but no enhancement in neutron-capture elements; [C/Fe] > +0.7 and [Ba/Fe] < 0.0), the origin of which has still not been identified with certainty. A number of lines of evidence (described in detail below) strongly suggest association of the CEMP-no stars with the nucleosynthesis products of the very first stars born in the Universe, i.e., that they are bona fide second-generation stars.

Aoki et al. (2002a) and Ryan et al. (2005) first called attention to the apparent contrast in the heavy-element abundance patterns among several sub-classes of CEMP stars, and speculated about their likely origin. In particular, Ryan et al. (2005) predicted that the binary fraction of the CEMP-no stars should be the same as for non carbon-enhanced, metal-poor stars, if they

acquired their carbon from the explosions of previous-generation massive stars. Moreover, Carollo et al. (2012, 2014) found the bulk of CEMP stars in the outer halo to be CEMP-no stars, while the CEMP-*s* stars appear to be predominantly associated with the inner halo – a finding of substantial, if as yet unclear, significance for our understanding of the formation of the haloes of galaxies, including our own.

The present series of papers considers the origin of chemically peculiar stars at very low metallicity, and tests whether their distinctive abundance signatures can be accounted for by alteration of their birth chemistry by an evolved binary companion, based on an eight-year programme of systematic, precise radial-velocity monitoring for larger samples of chemically peculiar stars than have heretofore been studied in this way.

What sets this entire project apart from earlier studies is our emphasis on high precision; the homogeneity of the data over a time span compatible with the periods of likely binaries in the sample; and our systematic follow-up of any suspected variable objects in the sample. This enables us to separate single stars and binaries on a rigorous, objective star-by-star basis.

Hansen et al. (2011) first showed that the enhancement of *r*-process elements observed in a small fraction (3-5%) of VMP and EMP stars is *not causally connected* to membership in a binary system, a conclusion that was confirmed and further strengthened in Paper I of this series (Hansen et al. 2015b). The present paper examines the same question for the class of CEMP-no stars, based on similarly precise and systematic radial-velocity monitoring. Paper III of this series addresses the role

¹ It should be noted that, even though progress is being made, the high fraction of CEMP-*s* stars found in the early Universe still poses a challenge for theoretical population synthesis modelling (e.g., Izzard et al. 2009; Abate et al. 2013, 2015).

that binaries play in the production of CEMP-*s* stars, using the same approach.

This paper is outlined as follows. Section 2 summarises our observing strategy and selection of programme stars, and briefly describes the observational techniques employed. The results are presented in Sect. 3. In Sect. 4, we discuss the constraints imposed by these results on the origin of CEMP-no stars, and outline the current evidence that they can be identified with the first stars able to form in the early Galaxy and Universe. Brief conclusions and thoughts on what can be learned from future radial-velocity monitoring of CEMP-no stars are presented in Sect. 5.

2. Observing strategy, observations, and data analysis

2.1. Observing strategy for this project

Previous forays into this subject (e.g., Lucatello et al. 2005; Starkenburg et al. 2014) have typically comprised a limited number of their own radial-velocity observations over a limited time span, sometimes combined with a literature search for earlier data, usually small in number and necessarily heterogeneous in origin. A Monte Carlo simulation was then used to assess the likely frequency of typical binaries in the sample.

Our approach throughout this project is completely different, building on the earlier examples of Duquennoy & Mayor (1991), Nordström et al. (1997), and Carney et al. (2003): To obtain a sufficient number of precise radial-velocity observations in a homogeneous system over a sufficiently long time span to detect any binaries in the sample, even if their orbital periods might be substantially longer than the time span of the observations (up to $\sim 2,900$ days in our case). Moreover, the observations are reduced promptly after each observing night, in order to rapidly detect any incipient variability and schedule follow-up observations as appropriate for each object, so the reality and origin of the variations could eventually be assessed with confidence.

As described in Paper I, this strategy enabled us to follow the star HE 1523–0901 over several orbital revolutions and identify it as a very low-inclination binary, despite its period of 303 days (\sim a year) and velocity semi-amplitude of only 0.35 km s^{-1} . In Paper III it has also enabled us to detect several binaries with periods of a decade or (much) more, although we ‘only’ followed them for $\leq 3,000$ days.

In such situations, the χ^2 statistic is a much more secure indicator of velocity variability for a given star than Monte Carlo simulations of variations in published data, although judgement must still be exercised in each case when reviewing the probability, $P(\chi^2)$, that a star is truly single. For example, the low-amplitude binary HE 1523–0901 has $P(\chi^2) < 10^{-6}$ (Paper I), while the CEMP-*s* star HE 0017–0055, classified as a long-period binary in Paper III, also exhibits an apparently similar, regular, short-period variation of period 385 days and amplitude 0.54 km s^{-1} , followed over 8 cycles. Yet, Jorissen et al. (2015) concluded, based on other evidence, that the short-period variations were due to pulsations rather than binary motion (see also the discussion of HE 1410+0213 below).

2.2. Sample selection

Our initial observing list, established in 2006, comprised a total of 23 CEMP stars with pedigrees of widely different quality, plus 17 *r*-process enhanced stars, drawn from the HK surveys of Beers, Preston, & Shectman (Beers et al. 1985,

1992) and the Hamburg/ESO survey of Christlieb and collaborators (Christlieb et al. 2008). The initial sample of CEMP stars also included one of the most metal-poor stars known to date, HE 1327–2326, with $[\text{Fe}/\text{H}] = -5.8$ (Aoki et al. 2006; Frebel et al. 2006).

By 2010, the overall conclusion of the *r*-process programme had already become clear (Hansen et al. 2011), while the significance of the different spatial distributions of the CEMP-*s* and CEMP-no subclasses, and the potentially different binary frequencies and origins of their carbon excess, had assumed greater importance. At the same time, our observing technique had been refined and amply tested as described above. From 2011, the *r*-process programme was therefore limited to sparsely sampled long-term monitoring, while 25 likely new CEMP-no stars were selected from the same sources and added to the regular programme. We then also included the bright CEMP-no star BD+44°493 in the programme, the abundance pattern of which has been studied extensively (Ito et al. 2013; Placco et al. 2014b). Ultimately, two of the candidate CEMP-no stars were shown not to be sufficiently carbon enhanced to be considered CEMP stars, and were dropped from our programme. In return, one of our candidate CEMP-*s* stars, to be discussed in Paper III, turned out to be a CEMP-no star and hence was moved to the sample discussed here.

Our final sample of 24 CEMP-no programme stars is provided in Table 1, which lists their *V* magnitudes, *B* – *V* colours, and reported $[\text{Fe}/\text{H}]$, $[\text{C}/\text{Fe}]$, and $[\text{Ba}/\text{Fe}]$ abundances (either from the literature or determined as described below).

2.3. Abundance information for the sample stars

As seen from Table 1, many of our sample stars have detailed abundance information available from high-resolution spectroscopy obtained with 6–10-m telescopes (the ‘First Stars’ project, e.g., Bonifacio et al. 2009, is a notable exception, since that project deliberately avoided carbon-enhanced stars). On that background, the present project at the 2.5-m Nordic Optical Telescope (NOT) focused on establishing the binary status of known CEMP stars.

Only five of the stars in our sample had no Ba abundance measurement in the published literature; one star (HE 0405–0526) lacked published estimates of $[\text{Fe}/\text{H}]$ and $[\text{C}/\text{Fe}]$ as well. For HE 0405–0526, we therefore derived estimates of $[\text{Fe}/\text{H}]$ and $[\text{C}/\text{Fe}]$ from a medium-resolution ($R \sim 2000$) spectrum obtained with the SOAR Telescope (program SO2011B-002), using the n-SSPP software pipeline described in detail by Beers et al. (2014). For this star, as well as for the remaining stars with initially missing Ba abundances, we have used the high-resolution spectra obtained for the radial-velocity monitoring. These have been co-added to produce a higher signal-to-noise ratio (SNR) spectrum, following the description in Paper I for co-add templates, but including only the orders containing the Ba lines at $\lambda = 4554 \text{ \AA}$ and $\lambda = 4934 \text{ \AA}$.

Barium abundances or upper limits were then obtained from spectral synthesis of these spectra, using the 2014 version of MOOG and the line list retrieved from the VALD database (Kupka et al. 1999), including hyperfine splitting and isotopic shifts. The Asplund et al. (2009) solar abundances have been assumed. The co-added spectra may have slightly broadened lines, due to the initial correlation when creating this spectrum, as described in Paper I, which could influence the abundances derived from these and result in a higher abundance estimate. We have

taken this into account when estimating the error on the derived abundances.

For three of the stars we considered, only an upper limit on the Ba abundance could be derived; however, all of these firmly classify the stars as CEMP-no stars. For HE 0405–0526 and HE 1133–0555, we derive Ba abundances of $[\text{Ba}/\text{Fe}] = -0.22$ and $[\text{Ba}/\text{Fe}] = -0.58$, respectively, with an estimated error of 0.3 dex, also classifying them as CEMP-no stars.

For the three stars CS 29527–015, HE 1012–1540, and HE 1327–2326, the derived Ba abundances or upper limits ($[\text{Ba}/\text{Fe}] < +0.10$, $[\text{Ba}/\text{Fe}] = +0.19$, and $[\text{Ba}/\text{Fe}] < +1.46$, respectively) do not qualify them as CEMP-no stars, based on the formal definition ($[\text{Ba}/\text{Fe}] < 0$). However, enhancement of the light elements has also been found to be associated with the CEMP-no sub-class; see the recent discussion by Norris et al. (2013b). For HE 1012–1540, Cohen et al. (2013) found $[\text{N}/\text{Fe}] = +1.25$, $[\text{O}/\text{Fe}] = +2.14$, $[\text{Na}/\text{Fe}] = +1.02$, and $[\text{Mg}/\text{Fe}] = +1.38$, while Frebel et al. (2008) derived $[\text{N}/\text{Fe}] = +4.53$, $[\text{O}/\text{Fe}] = +3.68$, $[\text{Na}/\text{Fe}] = +2.17$ and $[\text{Mg}/\text{Fe}] = +1.67$ for HE 1327–2326. Frebel et al. (2008) also obtained a relatively high Sr abundance for this star, $[\text{Sr}/\text{Fe}] = +0.98$. An absolute carbon abundance of $A(\text{C}) = \log \epsilon(\text{C}) = 6.06$ was reported for CS 29527–015 by Bonifacio et al. (2009), also pointing toward a CEMP-no classification for this star, but further observations are needed to confirm this.

2.4. Radial-velocity observations and data reduction

The observations, data reduction, and analysis procedures were those described in Paper I of this series, to which we refer the interested reader for details; only a brief summary is given here. Weather allowing, our programme stars were observed at roughly monthly intervals with the FIES spectrograph at the 2.5-m NOT on La Palma, Spain. The spectra cover a wavelength range of 3640 Å to 7360 Å at a resolving power of $R \sim 46,000$, and have an average SNR of 10. For obvious reasons, the stars added to the programme in 2010 were observed for shorter spans and, coupled with adverse spring weather conditions later, were observed less completely than stars from the initial sample.

Reductions and multi-order cross-correlation with a template spectrum were performed with software developed by L. Buchhave. The template spectrum used for a given star was either: The spectrum with maximum SNR (“strongest”); a co-added spectrum constructed from all the best spectra for the star (“Co-add”); a synthetic spectrum consisting of delta functions (“Delta”); or, finally, co-added spectra of the bright CEMP-no stars BD+44°493 or HE 0405–0526. The template used for each star is identified in Table 2.

Our error definitions and error analysis are also described in Paper I. Note especially that the standard deviations given in Tables 2 and 3 are the standard deviation of the radial velocity observations for each star, not standard errors of the mean.

The individual standard stars observed on this programme, along with their derived mean heliocentric radial velocities (RV) and standard deviations (σ), are listed in Table 2 of Paper I in this series; typical standard deviations are 40 m s^{−1} over a time span of ~2,800 days. The average difference of our mean velocities from the standard values is 73 m s^{−1} with a standard deviation of 69 m s^{−1}, demonstrating that our results are not limited by the stability of the FIES spectrograph.

Fig. 1. Radial-velocity history of BD+44°493 vs. time. *Blue* : This work, *green* : Carney et al. (2003), *yellow* : Ito et al. (2013), and *red* : Starkenburg et al. (2014). Dashed line: Global mean radial velocity; grey shaded areas: 1 σ and 2 σ regions around the global mean.

3. Results

The results of our radial-velocity observations for our CEMP-no stars are summarised in Table 2, which lists the number of observations (Nobs), the cross-correlation templates employed, the mean heliocentric radial velocity (RV mean) and standard deviation (σ) over the time span covered by our own observations (ΔT), and the binary status of each programme star. The individual observed heliocentric radial velocities are listed in Appendix A, together with the Julian dates of the observations and the corresponding internal errors.

As for the *r*-process-element enhanced stars discussed in Paper I, the external standard deviations of the observed velocities vary from < 100 m s^{−1} for the bright targets, dominated by centering and guiding errors, to ~ 1 km s^{−1} for the fainter and/or metal-poor targets with low-SNR spectra.

3.1. Comparison with published radial velocities for the constant stars

Radial-velocity observations for 16 of the programme stars without obvious velocity variations have been published previously, and may help to extend the time span of the data and strengthen our conclusion on their (non-) binary nature. We have searched the literature for velocities of the non-binary stars in our sample, based on moderate- to high-resolution spectra by authors who claim estimated velocity errors of ~ 1 km s^{−1} or better. Table B.1 in Appendix B summarises the results of this exercise. Note that these data are typically based on a single observation (or the mean of several closely spaced observations). In each case, the total time span given includes the oldest measurement that we consider reliable.

It is remarkable that *no* velocity in this comparison sample deviates from our own mean radial velocity by more than can be accounted for by the published errors, especially since the data was obtained with different spectrographs and were reduced and measured independently. As seen from the table, the observed time span for many of our programme stars now cover on the order of a decade or more. Clearly, if any of the stars we consider to be single are in fact members of a binary system, they are likely to have extremely long periods (but see discussion below).

An illustrative case is the bright star BD+44°493, which was also observed by Starkenburg et al. (2014). As seen from Table 2 and B.1, the radial velocities derived by Starkenburg et al.

Table 2. Star name; number of NOT observations; template used; mean heliocentric radial velocity and standard deviation; time span; variability criterion $P(\chi^2)$; and binary status.

(2014) are in excellent agreement with our derived velocities for both this and other constant stars (all except CS 29502–092 are within the stated 1- σ error bars; and CS 29502–092 agrees within 2 σ). Radial velocities for BD+44°493 were also reported by Carney et al. (2003) and Ito et al. (2013), whose measured mean velocities of -150.64 km s⁻¹ and -150.15 km s⁻¹, respectively, are both in excellent agreement with our result. The Carney et al. data are particularly valuable, since they enlarge the three-year time span of our own data by 13 years (1984 to 1997). Together, these four data sets contain 53 measurements spanning a total of 11368 days (~ 31 years) with a standard deviation of 0.63 km s⁻¹. Figure 1 shows all of the radial velocity data for BD+44°493 as a function of time. Clearly, this star is single.

Among the sources of literature data in Table B.1 (Appendix B), the only modern series of precise velocities with significant overlap with our programme are those by Starkenburg et al. (2014) and Roederer et al. (2014), whose velocity zero-points, moreover, agree with ours to within ~ 100 m s⁻¹. We have therefore included them in our χ^2 calculations as detailed in Table

3, whenever they could make a significant contribution to our results for the single stars.

3.2. Assessment of velocity variability

As discussed above, the data included here were obtained in a systematic manner and are of homogeneous quality, including the selected sources listed in Table 3. In this situation, the χ^2 statistic is the most objective and sensitive indicator of velocity variability as noted, e.g., by Carney et al. (2003).

In order to assess the binary status of our sample stars, we use the standard χ^2 criterion for velocity variability and compute the probability, $P(\chi^2)$, that the radial velocity is constant, based on the dispersion of the observed velocities vs. their associated internal errors (see Paper I for definitions). A “floor error” term of ~ 100 m s⁻¹ is added in quadrature to the internal error in order to account for external error sources such as variations in temperature or air pressure, atmospheric dispersion at high airmass, slit positioning, or imperfect guiding.

Observations correlated with the “Delta” template presented special difficulties, due to the small number of useful lines in each of few usable orders in our low-signal spectra. This situation may lead to large stochastic fluctuations in the internal mean error of individual velocities, so that velocities with normal uncertainty, but unusually small or large internal error estimates, completely dominate the overall value of χ^2 or, conversely, are effectively ignored. This is exacerbated in the limiting case of faint and/or extremely metal-poor stars at the limit of what is possible with a 2.5-m telescope, when observations obtained under poor conditions cause the correlation with a stellar spectrum to fail altogether.

Alternative attempts to estimate an average overall internal error were found to give results that were effectively biased towards either too small or too large errors. However, an average of the (large) mean of all internal errors and the (smaller) error of a mean observation of average weight was found to work reliably, and was adopted in such cases.

Adding the Starkenburg et al. (2014) and Roederer et al. (2014) data listed in Table 3, we then proceeded to calculate $P(\chi^2)$ for potentially single stars. The results, listed in Table 2, demonstrate that the great majority, 20 of our 24 programme stars, have constant radial velocities over the eight-year period of monitoring (i.e., they appear to be single), while four exhibit obvious radial-velocity variations that are clearly due to orbital motion.

However, limiting cases exist in which low-level variability may be interpreted as due to either motion in a nearly face-on binary orbit as in HE 1523–0901, or to pulsations like those in HE 0017+0055, as discussed in Sect. 2.1. Since so very nearly face-on binary orbits ($i \lesssim 1^\circ$) must be exceedingly rare, finding even one in such a modest sample raises immediate suspicions about its plausibility, such as discussed for the case of HE 1410+0213 in Sect. 3.3 below.

This finding raises another cautionary note concerning the use of Monte Carlo simulations to assess binary frequencies from samples of even accurate, but scattered radial-velocity observations: The limit to the estimated frequency of long-period binaries in the sample may be set by the presence of low-amplitude pulsations rather than merely by observational errors, if orbital motion is considered to be the only possible cause of small velocity variations in the error budget.

3.3. Binaries in our sample of CEMP-no stars

Four stars in our sample exhibited clear orbital motion during the monitoring period: HE 0219–1739, HE 1150–0428, HE 1506–0113, and CS 22957–027. We have determined orbits for three of these systems, combining our radial velocities with earlier, published data. The final orbital parameters for these systems are listed in Table 3, and the radial-velocity curves are shown in Fig. 2, including the literature data and total time spans as noted below. For the Starkenburg et al. (2014) data (red points in Fig. 2), we find an offset of only $\sim 18 \text{ m s}^{-1}$ between our data and theirs, based on six constant stars in common. For the data from Preston & Sneden (2001) (green points in Fig. 2), we have applied a correction of $\sim 1.84 \text{ km s}^{-1}$ to achieve consistency with our velocities.

For HE 1506–0113, we could combine our ten observations with the seven measurements by Starkenburg et al. (2014), which range from $\sim -80 \text{ km s}^{-1}$ to -90 km s^{-1} , in good agreement with our own results for this star (see Appendix). Combining them led to a plausible low-amplitude orbit with $P \sim 840 \text{ d}$ and modest eccentricity, although the data were insufficient to

Fig. 2. Orbit solutions for three of the four binaries found among our programme stars. Top: CS22057–027, middle: HE 1150–0428, and bottom: HE 0219–1739. Blue: This work; red: Starkenburg et al. (2014); green: Preston & Sneden (2001)

determine the orbital parameters with confidence. However, the four constant velocities of $\sim -137 \text{ km s}^{-1}$ from high-resolution VLT/UVES spectra reported by Norris et al. (2013a), spanning ~ 1 month in 2008, did not at all fit anything like this orbit,

Table 4. Orbital parameters for three of the binary systems identified in the sample

Table 5. Heliocentric radial velocities for HE 1506–0113 from UVES spectra.

HJD	RV	RV _{err}
2454650.630731	−54.58	0.631
2454651.628669	−56.57	0.705
2454653.519178	−56.67	0.530
2454672.486795	−53.60	0.674

but could be reconciled with a plausible highly-eccentric orbit of $P \sim 950$ d. Nonetheless, the resulting mass function of $f(m) \sim 0.5 M_{\odot}$ implied an impossibly high mass for the unseen companion, so this orbit was also rejected.

The large span of the observed velocities led us to re-examine the four archival UVES spectra more closely, and determine fresh radial velocities from them. The – very different – results are listed in Table 5 and plotted as a function of time in Figure 3. These new velocities are much *higher* than those reported earlier; they clearly vary over the short observing period ($P(\chi^2) = 0.001$), but delineate a shallow velocity *minimum* instead of the expected maximum, as is shown in the small inserted box in Figure 3.

Alternative explanations for this recalcitrant behaviour include a triple system, or a possible misidentification with a star of similar brightness 15'' SE of HE 1506–0113 itself, but solving this puzzle will require several more years of continued monitoring. In conclusion, and despite persistent effort, we have not been able to compute an orbit for this star, although it is clearly at least a binary.

Table 4 also lists the Roche-lobe radii for the present secondaries in the three binary systems for which we have computed orbits, calculated following the procedure described in Paper I and assuming present primary masses of $0.8 M_{\odot}$ and secondary masses of 0.4 and $1.4 M_{\odot}$, respectively. These are the lower and upper limits to the mass of a white dwarf (WD), which would be the likely remnant if the CEMP-no star were polluted by an initially more massive AGB star. As can be seen from Table 4, for the maximum WD mass ($1.4 M_{\odot}$), all of the systems could have accommodated an AGB star ($R \sim 200 R_{\odot}$), while for the lowest WD masses, the majority of the Roche-lobes would be too small.

**Fig. 3.** Radial-velocity data for HE 1506–0113. Blue: this work; red: Starkenburg et al. (2014); and black: re-analysed UVES spectra from Norris et al. (2013a). The inserted box is an enlargement of the RVs obtained from the UVES spectra.

Notes on individual stars:

Both Preston & Sneden (2001) and Starkenburg et al. (2014) found significant variations in the velocity of CS 22957–027, but were unable to determine the orbital period securely. Our own data did so, as kindly confirmed by Dr. G.W. Preston (priv. comm.), with the earlier data improving the period determination. Starkenburg et al. (2014) also reported large velocity variations in HE 1150–0428 and HE 1506–0113, but the data were too sparse to determine an orbital period. Our own, more complete data determine the orbit for HE 1150–0428 securely (see Fig. 2), while we have not been able to derive an acceptable orbital solution for HE 1506–0113, as discussed above.

HE 1410+0213 presented special difficulties, despite the large number of good observations (Table 2). With $P(\chi^2) < 10^{-4}$, its velocity is certainly variable, and some apparently systematic trends during individual years led us to suspect that it was a(nother) nearly face-on spectroscopic binary. Eventually, we were able to derive a plausible circular orbit with a period of ~ 330 days and a velocity amplitude of ~ 0.28 km s^{−1}. This, however, required an inclination of less than 1° , again highly unlikely in such a small sample of stars. Moreover, a later observation did not fit the putative orbit. We were thus faced with

a similar problem as for the CEMP-*s* star HE 0017+0055, discussed in Sect. 2.1 and in Paper III.

After much analysis, we conclude that HE 1410+0213 is most probably single, but exhibits low-amplitude pulsations of the kind described by Riebel et al. (2010) for C-rich variables in the LMC. Adding a velocity ‘jitter’ of 150 m s^{-1} then leads to the value of $P(\chi^2) = 0.196$ given in Table 2.

Mattsson (2015) describes how a combination of a strong stellar wind with such pulsations might enhance the mass loss from such an intrinsically bright EMP giant or AGB star. This could explain why the absolute carbon abundance of HE 1410+0213, places it in the “high-C band” of Spite et al. (2013), discussed further below.

Finally, Bonifacio et al. (2009) suggested that CS 29527–015 is a double-lined spectroscopic binary, due to asymmetries in the absorption lines detected in their high-resolution, high(er)-SNR UVES spectra. We find no evidence for this in our observations of the star, and with $P(\chi^2) = 0.992$, there is also no evidence for any binary motion, but additional high-resolution spectra may be required to settle the issue.

4. Discussion

Our sample of CEMP-no stars comprises 4 binaries and 20 single stars. We thus derive a binary frequency of $17 \pm 9\%$, identical to that found for the *r*-process-enhanced stars in Paper I of this series ($18\% \pm 11\%$)², and to the $16 \pm 4\%$ binary frequency found by Carney et al. (2003) in their study of 91 metal-poor ($[\text{Fe}/\text{H}] \leq -1.4$) field red giants.

4.1. Binary parameters and their implications

The four binary systems in our sample exhibit a similar combination of periods and eccentricities to those found by Carney et al. (2003) for metal-poor field red giants and dwarfs (see their Fig. 5), for Population I cluster giants by Mermilliod et al. (2007), and by us for the *r*-process-enhanced VMP and EMP stars discussed in Paper I (Hansen et al. 2015b). Figure 4 shows the period – eccentricity distribution for our binary stars (red plus signs), compared to the literature data from Mermilliod et al. (2007), Mathieu et al. (1990) (black dots), and Carney et al. (2003) (black crosses). The properties of our binary stars are thus completely indistinguishable from those of chemically normal population I and II giants, with HE 1150–0428 defining a cutoff period for circular orbits of old giant stars of ≥ 300 days, presumably due to the long time available for tidal circularisation.

This simple observational finding indicates that membership of a binary system has played no causal role in generating the dramatic carbon excess of the CEMP-no stars and rules out the local mass-transfer scenario for its origin. Instead, the excess carbon must have been produced elsewhere and implanted across interstellar distances into the natal cloud of the star we observe today – a process that is not included in standard models of the early chemical evolution of galaxy haloes.

4.2. Carbon bands

Spite et al. (2013) first suggested the existence of two bands in the absolute carbon abundances of CEMP stars – a high-C band at $A(\text{C}) \sim 8.25$ and a low-C band at $A(\text{C}) \sim 6.5$.

² Note that we have corrected the error on this frequency reported in Paper I, which was incorrectly stated to be $\pm 6\%$.

Fig. 4. Period - eccentricity distribution for the binary systems in our sample (red plus signs), compared to literature data, represented by black dots: Population I cluster giants (Mermilliod et al. 2007; Mathieu et al. 1990); and black crosses: Population I giants (Carney et al. 2003).

Fig. 5. Absolute carbon abundances, $A(\text{C}) = \log \epsilon(\text{C})$, of our programme stars, as a function of metallicity, $[\text{Fe}/\text{H}]$. Blue dots represent recognised binaries in our sample; red dots represent non-binaries. The high-C and low-C bands of Spite et al. (2013) are indicated by the horizontal lines.

Stars with carbon abundances on the lower band are more metal poor ($[\text{Fe}/\text{H}] \lesssim -3.0$) and mostly of the CEMP-no variety, while those on the higher band are relatively more metal rich ($[\text{Fe}/\text{H}] \gtrsim -3.0$), and primarily CEMP-*s* stars. They suggested that stars on the high-C band are members of binary systems that have been polluted by a companion AGB star, i.e., their carbon enhancement is *extrinsic*, whereas the stars on the low-C band were born from an ISM that had already been polluted by a (presumably) high-mass progenitor, i.e., the carbon enhancement is thus *intrinsic* to the star.

The existence of these two bands for CEMP stars has been confirmed with larger samples by Bonifacio et al. (2015) and Hansen et al. (2015a). Both of these samples find CEMP-no stars with carbon abundances placing them on the high-C band, but neither of these papers had sufficient information available to address the binary nature of their stars, and thereby more fully test the hypothesis for the astrophysical origin of the bands. Figure 5 shows the absolute carbon abundances of the stars in our sam-

ple as a function of metallicity; blue dots represent the detected binary stars and red dots represent the single stars.

As can be seen from inspection of Figure 5, three of our CEMP-no stars (HE 0219–1739, HE 1133–0555, and HE 1410+0213) have carbon abundances corresponding to the high-C band. HE 0219–1739 is a binary with ample space to accommodate a companion at the AGB stage in its Roche lobe for the assumed minimum and maximum masses ($0.4 M_{\odot}$ and $1.4 M_{\odot}$) of the putative white dwarf remnant (Table 3). HE 1410+0213 and HE 1133–0555 are both most likely single stars, but HE 1410+0213 is pulsating (see discussion above), which could enhance any mass loss by a strong stellar wind.

Two of the more metal-poor binary stars have carbon abundances that lie in the transition area between the two bands, around $[\text{Fe}/\text{H}] \sim -3.0$, where both CEMP-no and CEMP-*s* stars can be found. These two stars are HE 1150–0428 and CS 22957–027 (see Fig. 2), the former having a circular orbit with a period of $P = 290$ days, and the latter having a slightly eccentric orbit with a period of $P = 1080$ days. Only one of the stars with an absolute carbon abundance clearly on the low band is found to be in a binary system, HE 1506–0113. This star also exhibits high Na and Mg abundance ratios ($[\text{Na}/\text{Fe}] = +1.65$ and $[\text{Mg}/\text{Fe}] = +0.89$; Yong et al. 2013), signatures that are also found for many other CEMP-no stars (Norris et al. 2013b; Hansen et al. 2015a). It is worth noting that HE 1150–0428 also exhibits a high Na abundance $[\text{Na}/\text{Fe}] = +1.31$, but normal Mg abundance $[\text{Mg}/\text{Fe}] = +0.36$ (Cohen et al. 2013). For CS 22957–027, Cohen et al. (2013) report a high Na abundance ratio ($[\text{Na}/\text{Fe}] = +0.80$), but a low Mg ratio ($[\text{Mg}/\text{Fe}] = +0.11$), while Aoki et al. (2002c) obtain a higher Mg ratio ($[\text{Mg}/\text{Fe}] = +0.69$).

It is clearly highly desirable to obtain further information on the possible binary nature of the other six CEMP-no stars with carbon abundances on the high-C band, found in previous work (Bonifacio et al. 2015; Hansen et al. 2015a), and expand the sample of such stars. Should the majority turn out to be members of binary systems (rather unlikely in view of our present results), and in particular if there are signs that mass transfer has occurred, this would lend support to the existence of AGB stars that produce little if any *s*-process elements. A new nucleosynthesis process might then need to be invoked, or our understanding of the operation of the *s*-process at low metallicity must be improved. If these stars are also found to be single, another, distant production site must be invoked.

4.3. Evidence that CEMP-no stars are indeed second-generation stars

Our primary result from this paper confirms (with much-improved statistics) that mass transfer from a binary companion is not a necessary condition to account for the distinctive elemental-abundance patterns of CEMP-no stars. This is already strong evidence that they may indeed be bona fide second-generation stars, formed from an ISM polluted by a previous (possibly first-generation) population of stars. However, this is not the only evidence for this association. Here we briefly summarise the present observational constraints on this hypothesis.

- **The increased frequency of CEMP stars at low metallicity:** It has been recognised for over a decade that the relative numbers of CEMP stars (compared to C-normal stars) increases dramatically as $[\text{Fe}/\text{H}]$ declines from $[\text{Fe}/\text{H}] = -2.0$ to the most Fe-poor star known (SMSS J0313–6708, with $[\text{Fe}/\text{H}] \lesssim -7.8$; Keller et al. 2014; Bessell et al.

2015). Recent large samples of VMP and EMP stars from SDSS/SEGUE, e.g., Lee et al. (2013), have reinforced this result based on the thousands of CEMP stars found in this survey. It has also been shown that, at the lowest metallicities, the CEMP-no stars are the dominant sub-class of CEMP stars (Aoki et al. 2007; Norris et al. 2013b). Indeed, when limited to the sample of recognised or likely CEMP-no stars, the derived frequencies increase by 5–10% relative to CEMP stars when considered as a single class (Placco et al. 2014a). It has also been argued by Bromm & Loeb (2003) and Frebel et al. (2007a) that high C (and O) abundances facilitate low-mass star formation in the early Universe, resulting in the birth of long-lived C-enhanced stars.

- **The dominance of CEMP-no stars among C-enhanced stars at the lowest metallicity:** Aoki et al. (2007) found a clear difference in the metallicity distributions of CEMP-no and CEMP-*s* stars – the CEMP-no stars in their sample primarily occupy the lowest metallicity range (and are the only C-enhanced stars found below $[\text{Fe}/\text{H}] = -3.3$ in their sample). At even lower metallicities, seven of the eight stars known with $[\text{Fe}/\text{H}] < -4.5$: SMSS J0313–6708 ($[\text{Fe}/\text{H}] \leq -7.8$, Keller et al. 2014; Bessell et al. 2015); HE 1327–2326 ($[\text{Fe}/\text{H}] = -5.7$, Frebel et al. 2006; Aoki et al. 2006), HE 0107–5240 ($[\text{Fe}/\text{H}] = -5.4$, Christlieb et al. 2004), SDSS J1313–0019 ($[\text{Fe}/\text{H}] = -5.0$, Allende Prieto et al. 2015; Frebel et al. 2015), HE 0557–4840 ($[\text{Fe}/\text{H}] = -4.8$, Norris et al. 2007), SDSS J1742+2531 ($[\text{Fe}/\text{H}] = -4.8$, Bonifacio et al. 2015), SDSS J1029+1729 ($[\text{Fe}/\text{H}] = -4.7$, Caffau et al. 2011), and HE 0233–0343 ($[\text{Fe}/\text{H}] = -4.7$, Hansen et al. 2014) are CEMP-no stars. The star SDSS J035+0641 may be added to this list in the near future (Bonifacio et al. 2015 report $[\text{Ca}/\text{H}] = -5.0$). The lone exception is SDSS J1029+1729, for which Caffau et al. (2011) report $[\text{C}/\text{Fe}] \leq +0.9$, but higher SNR data is required in order to be certain of its status.
- **The sequence of the CEMP-no and EMP *r*-II stars:** As noted above, the composition of the (mostly single) CEMP-no stars is dominated by carbon, while the iron-peak elements are very weak ($[\text{Fe}/\text{H}] < -3.0$ to < -3.5). The strongly *r*-process-element enhanced (*r*-II) stars appear in a relatively narrow metallicity range near $[\text{Fe}/\text{H}] = -3.0$ and are mostly single, while the less-enhanced (i.e., more iron-rich) *r*-I stars have higher metallicities. However, the extreme *r*-II stars CS 31082–001 and HE 1523–0901, which are not C-rich, have absolute age determinations of ~ 13 –14 Gyrs from direct radioactive U/Th chronology (Hill et al. 2002; Frebel et al. 2007b), so one would reasonably expect the CEMP-no stars to be even older, at least in a chemical sense.
- **The bimodal distribution of *A*(C) for CEMP stars:** As discussed above, the recent recognition that the absolute carbon abundance of CEMP stars is apparently bimodal clearly indicates that a source of carbon production other than that associated with AGB stars is required in the early Universe.
- **The Li abundances of CEMP-no stars:** As discussed by Hansen et al. (2014) and references therein, the observed abundances of lithium for CEMP-no stars are *all* below the Spite Li plateau. While many of these stars may have had their Li depleted due to internal mixing during giant-branch

evolution, this does not apply to all cases (HE 1327–2326, for example, is a warm sub-giant with very low Li; several other such stars are listed in Masseron et al. 2012). This provides support for the suggestion by Piau et al. (2006) that Li astration by the progenitors associated with the production of carbon in the CEMP-no stars, followed by mixing with primordial gas, may well be involved.

– **The observed Be and B abundance limits for BD+44°493:**

The elements Be and B are thought to form in the early Universe exclusively by spallation reactions involving high-energy cosmic rays (Prantzos 2012), which implies that the abundances of these elements in CEMP-no stars should be uniformly low if they are indeed second-generation stars (due to the lack of a significant background cosmic-ray flux at these early times). Placco et al. (2014b) indeed reported very low upper limits for the abundances of Be and B in BD+44°493 ($\log \epsilon(\text{Be}) < -2.3$ and $\log \epsilon(\text{B}) < -0.7$). A low upper limit for Be ($\log \epsilon(\text{Be}) < -1.8$) was also previously found by Ito et al. (2013) for this star. Although future such observations (from the ground for Be, from space for B) are required for additional CEMP-no stars, the results for BD+44°493 are already compelling.

– **The association of CEMP-no stars with the outer-halo population of the Galaxy:**

Carollo et al. (2012) confirmed the early suggestion by Frebel et al. (2006; see also Beers et al., in prep.) that the fraction of CEMP stars increases with distance from the Galactic plane. The Carollo et al. study also showed a significant contrast in the frequency of CEMP stars between the inner- and outer-halo components of the Milky Way, with the outer halo having roughly twice the fraction of CEMP stars as the inner halo. They interpreted this as an indication that the progenitor population(s) of the outer halo likely had additional astrophysical sources of carbon production, beyond the AGB sources that may dominate for inner-halo stars.

Subsequently, Carollo et al. (2014) offered evidence that the CEMP-*s* stars are preferentially associated with the inner-halo population, while the CEMP-no stars appear more strongly associated with the outer-halo population. As pointed out by Carollo et al. (2014), recent hierarchical galaxy-formation simulations suggest that the inner-halo population of the Milky Way arose from the assembly of relatively more-massive sub-galactic fragments (capable of supporting extended star formation, hence reaching higher metallicities), while the outer-halo population comprises stars formed in relatively less-massive fragments (which experienced short or truncated star-formation histories, and hence produced stars of lower metallicity). This, and other lines of evidence (e.g., the likely flatter IMF associated with star formation in the early Universe; Tumlinson 2007) suggests that the dominant progenitors of CEMP stars in the two halo components were different; massive stars for the outer halo, and intermediate-mass stars in the case of the inner halo.

– **The discovery of damped Ly-alpha systems with enhanced carbon:**

Cooke et al. (2011, 2012) have reported on recently discovered high-redshift carbon-enhanced damped Ly-alpha systems that exhibit elemental-abundance patterns which resemble those from that expected from massive, carbon-producing first stars, and speculated that these progenitors are the same as those responsible for the abundance

patterns associated with CEMP-no stars in the Galaxy. To our knowledge, this is one of the first cases, if not *the* first, of evidence for a direct linkage between the observed abundances in cosmologically distant objects with local extremely metal-poor stars. It also underscores our main conclusion that the excess carbon was not provided by a binary companion, but was produced elsewhere and transported across interstellar distances through the early ISM.

5. Conclusions and outlook

We have systematically monitored the radial velocities for a sample of 24 CEMP-no stars for time spans of up to eight years, and confidently identify a total of four binary systems. We have identified a number of other CEMP-no stars in the literature, not included in our own programme, which similarly exhibit no signs of binarity. These include the hyper metal-poor star HE 0107–5240, with $RV_{\text{mean}} = 44.5 \text{ km s}^{-1}$ and $\sigma = 0.3 \text{ km s}^{-1}$ (31 measurements from 2001 to 2006; N. Christlieb priv. comm), the ultra metal-poor star HE 0557–4840, with $RV_{\text{mean}} = 211.7 \text{ km s}^{-1}$ and $\sigma = 0.2 \text{ km s}^{-1}$ over 2193 days (Norris et al. 2007, 2012), and the EMP star CD –24°17504, with $RV_{\text{mean}} = 136.6 \text{ km s}^{-1}$ and $\sigma = 0.7 \text{ km s}^{-1}$ over 4739 days (Norris et al. 2001; Aoki et al. 2009; Jacobson et al. 2015b). All of these stars have carbon abundances on the low-C band, whereas the majority of our detected binary stars have carbon abundances either in the transition area between the two bands, an area populated by both CEMP-no and CEMP-*s* stars, or on the high-C band.

There clearly is a need for additional RV-monitoring observations of CEMP-no (and CEMP-*s*) stars (see Paper III of this series), and detailed abundance analyses of these stars, in order to identify more examples of high/low carbon-band associations, and to better understand the astrophysical implications. The ongoing survey by Placco et al. to detect bright CEMP targets from among RAVE stars with $[\text{Fe}/\text{H}] < -2$ (Kordopatis et al. 2013) will be an ideal source of candidates for radial-velocity monitoring, once they can be confirmed as CEMP-no or CEMP-*s* stars. In addition, stars emerging from surveys such as SkyMapper (Keller et al. 2007, 2014; Jacobson et al. 2015a), the TOPoS survey of SDSS/SEGUE turnoff stars (Caffau et al. 2013; Bonifacio et al. 2015), and LAMOST (Deng et al. 2012; Li et al. 2015) will help to further populate and confirm the existence of the two carbon bands.

We conclude that there now exists compelling evidence that the CEMP-no stars are among the first low-mass stars to form in the early Universe, and as such they contain the chemical imprints of the very first stars in their natal clouds in the early ISM. The prime candidates for production of large amounts of carbon in the early Universe are faint supernovae with mixing and fallback (Umeda & Nomoto 2003; Nomoto et al. 2013) and massive, rapidly rotating metal-free stars, the so-called “spinstars” (Meynet et al. 2006; Hirschi 2007; Maeder et al. 2015).

Thus far, no clear distinction between the abundance patterns of these two scenarios has been found, either in the models or in the derived abundances of the CEMP-no stars. The observed large over-abundances of carbon and nitrogen are well-reproduced by both models. The spinstar model can also explain other signatures found in CEMP-no stars, such as low $^{12}\text{C}/^{13}\text{C}$ isotopic ratios, and high Na, Mg, Al and Sr abundances (Maeder et al. 2015), while Tominaga et al. (2014) was able to fit the abundance patterns of 12 CEMP-no stars, from C to to Zn, with yields from mixing and fallback SNe models.

However, at present none of the suggested progenitors can explain the full range of elements for which abundances

are derived for CEMP-no stars – the light-elements, the α -elements, the iron-peak elements, and the neutron-capture elements. Hence, as suggested by Takahashi et al. (2014), the observed abundance patterns of CEMP-no stars (perhaps in particular those in the transition area between the low-C and high-C bands) could arise from a combination of the two suggested progenitors, or another primordial source that has yet to be identified. Detailed abundance analyses of larger samples of CEMP-no stars will help to settle this question.

Acknowledgements. We thank several NOT staff members and students for obtaining most of the FIES observations for us in service mode during this large project. We thank Piercarlo Bonifacio and Monique Spite for sharing their previously obtained spectrum of CS 29527-015, and obtaining a new upper limit on the [Ba/Fe] ratio for this star, George Preston for very kindly sharing his own observations of CS 22957-027, and Norbert Christlieb for sharing his RV data for HE 0107-5240 with us. We also thank Heather Jacobsen for advice on the best available historical RV data for CD-24°17504, and David Yong for helping to clarify some of the mystery regarding HE 1506-0113. Furthermore, we express our cordial thanks to the referee for an incisive and helpful report, which led to substantial improvements in the paper. T.T.H. was supported during this work by Sonderforschungsbereich SFB 881 “The Milky Way System” (subproject A4) of the German Research Foundation (DFG). J.A. and B.N. gratefully acknowledge financial support from the Danish Natural Science Research Council and the Carlsberg Foundation, and T.C.B., V.M.P., and J.Y. acknowledge partial support for this work from grants PHY 08-22648; Physics Frontier Center/Joint Institute or Nuclear Astrophysics (JINA), and PHY 14-30152; Physics Frontier Center/JINA Center for the Evolution of the Elements (JINA-CEE), awarded by the US National Science Foundation. This paper is based primarily on observations made with the Nordic Optical Telescope, operated by the Nordic Optical Telescope Scientific Association at the Observatorio del Roque de los Muchachos, La Palma, Spain, of the Instituto de Astrofísica de Canarias. It is also based on observations obtained at the Southern Astrophysical Research (SOAR) telescope, which is a joint project of the Ministério da Ciência, Tecnologia, e Inovação (MCTI) da República Federativa do Brasil, the U.S. National Optical Astronomy Observatory (NOAO), the University of North Carolina at Chapel Hill (UNC), and Michigan State University (MSU).
